Unisense microsensors in medical biofilm research

O₂ and N₂O microprofiles in sputum samples from cystic fibrosis patients with chronic *Pseudomonas aeruginosa* lung infection

**Introduction**

With the Unisense microsensors and the Unisense MicroProfiling System you can complete microprofiles in biofilms with extreme positioning accuracy (precision < 10 µm) and high spatial resolution to obtain valuable information about the microenvironment.

Kolpen et al. (2014) used the Unisense O₂ and N₂O microsensors to measure microprofiles in sputum samples from cystic fibrosis patients with chronic *Pseudomonas aeruginosa* infection. *P. aeruginosa* is the major cause of chronic lung infection of cystic fibrosis patients where the bacteria live as biofilm aggregates in the lungs. The biofilms can persist for years in the airways of the patient despite an active immune response and antibiotic therapy. The measurements in the paper by Kolpen et al. provided new insights about the microenvironment and growth of the *P. aeruginosa* biofilm which may lead to new treatment strategies.

**Laboratory setup**

The authors used the Unisense O₂ and N₂O microsensors both having a tip diameter of 25 µm (OX-25 and N₂O-25). The microsensors were connected to an Unisense amplifier and mounted on the motorized Unisense MicroProfiling System (Figure 1). The glass vials containing the freshly expectorated sputum samples were kept at 37 °C during the measurement. The sensors were first positioned manually at the upper surface of the sputum sample using the micromanipulator (MM33) to define the surface of the sample as the zero depth. Then the motorized MicroProfiling System was used to do automated microprofiles vertically through the sputum samples. The SensorTrace Profiling software controlled the movement of the microsensors and the authors used a step size of 100 or 200 µm, a waiting time between measurements of 3 seconds for the O₂ profile and 5 seconds for the N₂O profile, and a delay time between each cycle of profile measurements of 10 seconds. Data acquisition and analysis were done with the SensorTrace Profiling software that logs the measured analyte concentration together with the depth position of the micromanipulator.

Results and conclusion

Based on the O₂ and N₂O microsensor profiling measurements, the authors demonstrated that sputum samples from patients with chronic *P. aeruginosa* infection consist of an upper oxygenated zone and a lower anoxic zone below around 3 mm from the sputum surface (Figure 2). N₂O production from the bacteria was mainly confined to the lower anoxic part and a maximum median concentration of 41.8 µM N₂O was found. Significantly less N₂O was found in control sputum samples from cystic fibrosis patients without infection. N₂O is an intermediate in the denitrification pathway and the data indicated that *P. aeruginosa* may acquire energy for growth from denitrification when O₂ is absent.

Using the Unisense microsensors to obtain O₂ and N₂O concentration gradients with high spatial resolution, the authors could explore the microenvironment in the sputum and they demonstrated N₂O production in clinical samples from infected cystic fibrosis patients for the first time.
